

# Review of Benthic Substrates for Micronesia's Coral-Reef Monitoring Programs Using Coral Reef Point Count Software

# Focus of presentation

- To help identify and become comfortable with the most common benthic substrates from photo-quadrat data used by monitoring programs
- Not focused on identifying coral genera, see other materials for coral taxonomy
- Focused upon common substrates other than corals that are good indicators of reef 'condition'
- Can be expanded upon later, send recommendations for what to include

Examples of common benthic  
substrates other than corals

# CCA

- Crustose coralline algae
  - Reef cementers, help glue reef structure together, heavily calcified
  - Many coral larvae shown to preferentially settle on CCA versus other substrates
  - *Hydrolithon*, *Porolithon*, and *Titanoderma* are some key genera
  - Typically lighter shades of pink and purple
  - CCA are most often associated with healthy reefs (+)

# FCA

- Fleshy coralline algae
  - Less influential reef cementers, often only partially calcified
  - FCA have been shown to shed their outer epidermal layer when coral larvae try and settle
  - FCA known for more rapid lateral growth, with the ability to shade even adult coral colonies
  - *Peyssonnelia* and *Pneophyllum* are some key genera
  - Typically darker shades of pink, purple, brown, or mottled
  - FCA are known to be more abundant on unhealthy reefs (-) in comparison to CCA

# BCA

- Branching coralline algae
  - Heavily calcified branching algae, typically found around inner reef habitats and lagoons
  - *Neogoniolithon* and *Porolithon* some key genera for BCA species
  - Can be mistaken for coral growth, most notably *Pocillopora damicornis*, but pink/white color is distinguishing
  - BCA are not fully considered to be (+) or (-) indicators to healthy reefs, for now we consider neutral

# Turf

- Turf algae
  - Comprised mainly of microalgae often belonging to the family Gelidiaceae
  - However, all erect algal substrates less than 2 cm in height are typically classified as turfs
  - Typically looks like fuzzy substrate of varying color (dark brown, green, and red are most common)
  - Macroalgae greater than 2 cm in height are typically classified by genus in coral point count software

# Some examples of photographs analyzed from Pohnpei

- Note
  - No two people will score every data point the same every time
  - However, on average similar scoring of benthic substrates should exist

Average of BSR

BSR – Benthic substrate ratio, or the ratio of calcifying substrates (i.e., good) to non-calcifying substrates (i.e., bad). This measure is one of the key indicators used to evaluate things like the MC.
